

The Art of Iterating: Update-Strategies in Agent-Based Simulations

Jonathan THALER

January 30, 2017

Abstract

When developing a model for an Agent-Based Simulation (ABS) it is of very importance to select the right update-strategy for the agents to produce the desired results. In this paper we develop a systematic treatment of all general properties, derive the possible update-strategies in ABS and discuss their interpretation and semantics something which is still lacking in the literature on ABS. Further we investigate the suitability of the three very different programming languages Java, Haskell and Scala with Actors to implement each of the update-strategies. Thus this papers contribution is the development of a new, general terminology of update-strategies and their implementation comparison in various kinds of programming languages.

1 Introduction

In the paper of [8] the authors showed that the results of the simulation of the classic prisoners-dilemma on a 2D-grid reported in [10] depends on a very specific strategy of iterating this simulation and show that the beautiful patterns as reported by [10] will not form when selecting a different iteration-strategy. Although the authors differentiated between two strategies, their description still lacks precision and generality which we will try to repair in this paper. Although they too discussed philosophical aspects of choosing one strategy over the other, they lacked to generalize their observation. We will do so in the central message of our paper by stressing that when

doing Agent-Based Simulation & Modelling (ABS) *it is of most importance to select the right iteration-strategy which reflects and supports the corresponding semantics of the model.* We find that this awareness is yet still under-represented in the literature of ABS and lacking a systematic treatment. Thus our contribution in this paper is to provide a such by

- Presenting all the general properties and deriving update-strategies which are possible in an ABS.
- Developing a new, general terminology of talking about them.
- Giving the semantic interpretation and meaning of each of them.
- Comparing the 3 programming languages Java, Haskell and Scala with Actors in regard of their suitability to implement each of these strategies.

Besides the systematic treatment of all the general update-strategies the paper presents another novelty which is its inclusion of the pure functional declarative language Haskell in the comparison. This language has so far been neglected by the ABS community which is dominated by object-oriented (OO) programming languages like Java thus the usage of Haskell presents a real, original novelty in this paper.

2 Related Research

Already noted in the introduction, [8] where the first to discuss the differences update-strategies can make

and introduced the terms of synchronous and asynchronous updates. They define to be synchronous as Agents being updated in unison and asynchronous where one Agent is updated and the others are held constant.

[1] give an approach for ABS on GPUs a very different approach to updating and iterating Agents in ABS. They discuss execution order at length, highlight the problem of inducing a specific execution-order in a Model which is problematic for parallel execution and give solutions how to circumvent these shortcomings. Although we haven't mapped our ideas to GPUs we explicitly include an approach for data-parallelism which, we hypothesize, can be utilized to roughly mapped their approach into our terminology.

[3] sketch a minimal agent-framework in Haskell which is very similar in the basic structure of ours. This proves that this approach, very well developed in ABS, seems to be a very natural one also to apply to Haskell. Their focus is more on economic simulations and instead of iterating a simulation with a global time, their focus is on how to synchronize agents which have internal, local transition times. Although their work uses Haskell as well, this does not diminish the novelty of our approach using Haskell because our focus is a very different from them and approaches ABS in a more general and comprehensive sense.

[5] describe basic inner workings of ABS environments and compare their implementation in C++ to the existing ABS Environment AnyLogic which is programmed in Java. They explicitly mention asynchronous and synchronous time models and compare them in theory but unfortunately couldn't report the results of asynchronous updates due to limited space. They interpret asynchronous time-models to be the ones in which an Agent acts at random time intervals and synchronous time-models where agents are updated in same time intervals.

[12] presents in his Master-Thesis a comprehensive discussion on how to implement an ABS for state-charts in Java and also mentions synchronous and asynchronous time-model. He identifies the asynchronous time-model to be one in which updates

are triggered by the exchange of messages and the synchronous ones which trigger changes immediately without the indirection of messages.

We observe that there seems to be a variety of meanings attributed to the terminology of asynchronous vs. synchronous updates but the very semantic and technical details are unclear and not described very precisely. In the section about a new terminology we will address this issue and will put forward a proposal of how to fit these differences into our update-strategies and speak in a consistent way about them. there is no consistent use and understanding of it in the literature of ABS. Also it is imprecise and lacking important details which are of importance for the semantics of a Model. Thus we argue that there is still a lack of awareness about the influence of results due to the lack of important properties.

3 Background

3.1 Agent-Based Simulation

ABS is a method of modelling and simulating a system where the global behaviour may be unknown but the behaviour and interactions of the parts making up the system is of knowledge. Those parts, called Agents, are modelled and simulated out of which then the aggregate global behaviour of the whole system emerges. Thus the central aspect of ABS is the concept of an Agent which can be understood as a metaphor for a unique pro-active unit, able to spawn new Agents, interacting with other Agents in a network of neighbours by exchange of messages which are situated in a generic environment [11]. Thus we informally assume the following about our Agents:

- They have a unique identifier and some internal state
- They can initiate actions on their own e.g. change their internal state, send messages, create new agents, kill themselves,...
- They can react to messages they receive with actions (see above)

- They can interact with a generic environment they are situated in

An implementation of an ABS must thus solve two fundamental problems:

1. Source of pro-activity
How can an Agent initiate actions without the external stimuli of messages?
2. Semantics of Messaging
When is a message m , sent by Agent A to Agent B , visible and processed by B ?

In computer systems, pro-activity, the ability to initiate actions on its own without external stimuli, is only possible when there is some internal stimuli, most naturally represented by some generic notion of monotonic increasing time-flow. Due to the discrete nature of computer-system, this time-flow must be discretized in steps as well and each step must be made available to the Agent, acting as the internal stimuli. This allows the Agent then to perceive time and become pro-active depending on time. Independent of the representation of the time-flow we have the two fundamental choices whether the time-flow is local to the Agent or whether it is a system-global time-flow. Time-flows in computer-systems can only be created through threads of execution thus there are two ways of feeding time-flow into an Agent. Either it has its own thread-of-execution or the system creates the illusions of their own thread-of-execution by sharing the global thread-of-execution sequentially among the Agents where an Agent has to yield the execution back after it has executed its step. Note the parallels to an operating system with cooperative multitasking in the latter case and real multi-processing in the former.

The semantics of messaging define when sent messages are visible to the receivers and when the receivers process them. Message-processing could be either immediately or delayed, depending on how message-delivery works. There are two ways of message-delivery: queued or immediate. In the case of immediate message-deliver the message is sent directly to the Agent without any queuing in between

e.g. a direct method-call. This would allow an Agent to immediately react to this message as this call of the method transfers the thread-of-execution to the Agent. This is not the case in the queued message-delivery where messages are posted to the message-box of an Agent and the Agent pro-actively processes the message-box at regular points in time.

3.2 ABS Properties

To develop a new terminology, we propose to abandon the notion of synchronous and asynchronous updates and, based on the discussion above we derived six properties characterizing the dimensions and details of the internals of an ABS:

Iteration-Order Is the collection of Agents updated *sequential* with one Agent updated after the other or are all Agents updated in *parallel*, at virtually the same time?

Iteration-Synchronization Is a full Iteration over the collection of Agents happening in lock-step at *synchronous* points in time or does it happen for each agent individually *asynchronous*?

Thread of Execution Does each Agent has a *separate* thread-of-execution or does it *share* it with all the others? Note that it seems to have a constraint on the Iteration-Order, namely that *parallel* execution forces separate threads of execution for all Agents. We will show that this is not the case, when looking at the Parallel Strategy in the next section.

Message-Handling Are messages handled *immediately* by an Agent when sent to them or are they *queued* and processed later? Here we have the constraint, that an immediate reaction to messages is only possible when the Agents share a common thread of execution. Note that we must enforce this constraint as otherwise Agents could end up having more than one threads-of-execution which could result in them acting concurrently by making simultaneous actions. This is something we explicitly forbid

as it runs against our definition of Agents which allows them only one thread-of-execution at a time.

Visibility of Changes Are the changes made (messages sent, environment modified) by an Agent which is updated during an Iteration-Order visible (during) *In-Iteration* or only *Post-Iteration* at the next Iteration-Order? More formally: do all the Agents $a_{n>i}$ which are updated after Agent a_i see the changes to the environment and messages sent to them by Agent a_i ?

Repeatability May repeated runs lead to different results with the same configuration? If this is the case then the update-strategy is regarded as *non-deterministic* and *deterministic* otherwise.

Having these properties identified we can now move on to derive all meaningful and reasonable update-strategies which are possible in a general form in ABS. These update-strategies together with the properties will form the new terminology we propose to speak about update-strategies in ABS in general.

4 Update-Strategies

In this section we present the four general update-strategies which are possible in ABS. We give the list of all properties presented in the previous section, give a short description of the strategy and discuss their semantics and variations. We will discuss all details programming-language agnostic, give semantic meanings and interpretations of them and the implications selecting update-strategies for a model.

4.1 Sequential Strategy

Iteration-Order: Sequential

Iteration-Synchronization: Synchronous

Thread of Execution: Shared

Message-Handling: Immediate or Queued

Visibility of Changes: In-Iteration

Repeatability: Deterministic

Description: This strategy has a global time-flow and in each time-step iterates through all the agents

and updates one Agent after another. Messages sent and changes to the environment made by Agents are visible immediately.

Semantics: There is no source of randomness and non-determinism thus rendering this strategy to be completely deterministic in each step. Messages can be processed either immediately or queued depending on the semantics of the model. If the model requires to process the messages immediately the model must be free of potential recursions.

Variation: If the sequential iteration from 1..n imposes an advantage over the Agents further ahead or behind in the queue (e.g. if it is of benefit when making choices earlier than others in auctions or later when more information is available) then one could use random-walk iteration where in each time-step the agents are shuffled before iterated. Note that although this would introduce randomness in the model the source is a random-number generator thus reproduce-able.

Using this strategy it is very easy to create the illusion of a local-time for each agent by adding a random-offset to the global time for every Agent.

If one wants to have a very specific ordering (e.g. 'better performing' Agents first) then this can be easily implemented too by exposing some sorting-criterion and then sorting the list of agents.

4.2 Parallel Strategy

Iteration-Order: Parallel

Iteration-Synchronization: Synchronous

Thread of Execution: Separate (or Shared)

Message-Handling: Queued

Visibility of Changes: Post-Iteration

Repeatability: Deterministic

Description: This strategy has a global time-flow and in each time-step iterates through all the agents and updates all Agents in parallel. Messages sent and changes to the environment made by Agents are visible in the next global step. We can think about

this strategy that all Agents make their moves at the same time.

Semantics: If one wants to change the environment in a way that it would be visible to other Agents this is regarded as a systematic error in this strategy. First it is not logical because all actions are meant to happen at the same time and also it would implicitly induce an ordering thus violating the *happens at the same time* idea. Thus we require different semantics for accessing the environment in this strategy. We introduce thus a *global* environment which is made up of the set of *local* environments. Each local environment is owned by an Agent thus there are as many local environments as there are Agents. The semantics are then as follows: in each step all Agents can *read* the global environment and *read/write* their local environment. The changes to a local environment are only visible *after* the local step and can be fed back into the global environment after the parallel processing of the Agents.

It does not make a difference if the Agents are really computed in parallel or just sequentially, due to the semantics of changes, this has the same effect. In this case it will make no difference how we iterate over the agents (sequentially, randomly), the outcome *has to be* the same - it is event-ordering invariant as all events/updates happen *virtually* at the *same time*. Thus if one needs to have the semantics of writes on the whole (global) environment in ones model, then this strategy is not the right one and one should resort to one of the other strategies.

Variation: Using this strategy it is very easy to create the illusion of a local-time for each agent by adding a random-offset to the global time for every Agent.

4.3 Concurrent Strategy

Iteration-Order: Parallel
Iteration-Synchronization: Synchronous
Thread of Execution: Separate
Message-Handling: Queued
Visibility of Changes: In-Iteration
Repeatability: Non-Deterministic

Description: This strategy has a global time-flow and in each time-step iterates through all the agents and updates all Agents in parallel but all messages sent and changes to the environment are immediately visible. Thus this strategy can be understood as a mix of Seq and Par: all Agents run at the same time with actions becoming immediately visible.

Semantics: It is important to realize that, when running Agents in parallel which are able to see actions by others immediately, this is the very definition of concurrency: parallel execution with mutual read/write access to shared data. Of course this shared data-access needs to be synchronized which in turn will introduce event-orderings in the execution of the Agents. Thus at this point we have a source of inherent non-determinism: although we would ignore any hardware-model of concurrency at some point we need arbitration to decide which Agent gets access first to a shared resource thus arriving at non-deterministic solutions - this will become much clearer in the results-section. This has the very important influence that repeated runs with the same configuration of the Agents and the Model may lead to different results each time.

Variation: Using this strategy it is very easy to create the illusion of a local-time for each agent by adding a random-offset to the global time for every Agent.

4.4 Actor Strategy

Iteration-Order: Parallel
Iteration-Synchronization: Asynchronous
Thread of Execution: Separate
Message-Handling: Queued
Visibility of Changes: In-Iteration
Repeatability: Non-Deterministic

Description: This strategy has no global time-flow but all the Agents run concurrently in parallel, with their own local time-flow. The messages and changes to the environment are visible as soon as the data arrive at the local Agents - this can be immediately

when running locally on a multi-processor or with a significant delay when running in a cluster over a network. Obviously this is also a non-deterministic strategy and repeated runs with the same Agent and Model-configuration may (and will) lead to different results.

Semantics: It is of most importance to note that information and thus also time in this strategy is always local to an Agent as each Agent progresses in its own speed through the simulation. Thus in this case one needs to explicitly *observe* an Agent when one wants to e.g. visualize it. This observation is then only valid for this current point in time, local to the observer but not to the Agent itself, which may have changed immediately after the observation. This implies that we need to sample our Agents with observations when wanting to visualize them, which would inherently lead to well known sampling issues. A solution would be to invert the problem and create an Observer-Agent which is known to all Agents where each Agent sends a *'I have changed'* message with the necessary information to the observer if it has changed its internal state. This also does not guarantee that the observations will really reflect the actual state the Agent is in but is a remedy against the notorious sampling.

This is the most general one of all the strategies as it can emulate all the others by introducing the necessary synchronization mechanisms and Agents. Also this concept was proposed by C. Hewitt in 1973 in his work [7] where upon I. Grief in [6] and W. Clinger in [4] developed semantics of different kinds. These works were very influential in the development of the Agent-Term and concept and can be regarded as foundational basics for ABM/S.

Variation: It is important to understand that this strategy is the most general one as it allows to simulate all other strategies using synchronization.

5 Implementation ¹

In this section we give a brief overview of comparing implementing the update-strategies in three languages which fundamentally differ among each other. We wanted to cover a wide range of different types of languages but didn't include a language where the memory-management falls in the hands of the developer. This would be the case e.g. in C++. This was looked into partially by [5] but the focus of this paper is not on this issue as it would complicate things dramatically. All used languages are garbage-collected / the developer does not need to care how memory is cleared up.

For testing the suitability we selected a variety of simple models we implemented in each language with mostly all strategies. The selected models are *Heroes & Cowards*, *SIRS*, *Wildfire* and the *Spatial Game* mentioned in [8]. We lack the space to explain all models but all are well known and can be easily found, looked up and understood on the Internet. They span different challenges to the ABS implementation: sending messages, accessing the environment, spawning new Agents, killing existing ones, discrete and continuous model. We also can confirm that all the reference-models proposed in [9] and the StupidModel 1-16 by Railsback (TODO: cite) can be faithfully capture using our new terminology. Also we could show that the Parallel-Strategy is the only strategy able to reproduce the pattern of the *Spatial Game* due to the semantics of the model which require that all the Agents play the game at virtually the same time - which is only possible in the Parallel-Strategy.

5.1 Java

This language is included as the benchmark of object-oriented (OO) imperative languages as it is extremely popular in the ABS community and widely used in implementing their models and Environments. It comes with a comprehensive programming library, has nice object-oriented features built in and

¹Code available under
<https://github.com/thalerjonathan/phd/tree/master/coding/papers/iteratingABM/>

powerful synchronization primitives at built in at language-level.

Ease of Use Being experienced Java-Programmers we found that implementing all the strategies was straight-forward and easy thanks to the languages features. Especially parallelism and concurrency is quite very easy due to elegant and powerful built-in synchronization primitives.

Benefits We experienced quite high-performance even for a large number of agents which we attributed to aliasing using references and side-effects. This prevents massive copying like in the case of Haskell, where we found the performance to be quite low.

Deficits We couldn't identify something which absolutely didn't work, that's also why Java can be regarded as a very safe decision when opting which language to use for implementing ABS. A downside is that one must take care when accessing memory in case of parallel or concurrent strategy. Due to the availability of aliasing and side-effects in the language and the type-system, it can't be guaranteed that access to memory happens only when its safe - something which is possible in Haskell (see below). Care must be taken when references are sent by messages to other agents in case of parallel or concurrency although the interfaces encourage it we cannot prevent the agents to use agent-references and directly accessing. a workaround would be to create new agent-instances in every iteration-step which would make old references useless but this doesn't protect us from concurrency issues with a current iteration (the copying must take place within a synchronized block, thus implicitly assuming ordering, something we don't want) and besides, can always work around and update the references. that's the toll of side-effects: faster execution but less control over abuse tried to clone agents in each step and let them collect their messages => extremely slow

Natural Strategy We think that the Sequential Strategy with Immediate Message-Handling is the

most natural Strategy to express in Java due to its heavy reliance on side-effects through references (aliases) and shared thread of execution. Also most of the models work this way and its thus a save decision to start with Java.

5.2 Haskell

This language is included to put to test whether such a pure functional declarative programming language is suitable for full-blown ABS. What distinguishes it is its complete lack of implicit side-effects, global data, mutable variables and objects. The central concept is the function into which all data has to be passed in and out explicitly through statically typed arguments and return values: data-flow is completely explicit.

Ease of Use Being Haskell-Beginners we initially thought that it would be suitable at best for just implementing the Parallel-Strategy but after implementing all we came to the conclusion, that Haskell is extremely well suited to implement all of them. We think this stems from the facts that it has no implicit side-effects which reduces bugs considerably and results in very explicit data-flow.

Not having objects with data and methods which can call between each other meant, that we needed some different way of representing Agents. This was done using a struct-like type to carry data and a transformer function which would receive and process messages. This may seem to look like OO but it is not: Agents are not carried around but messages are sent to a receiver identified by an id.

Benefits We really enjoyed working in the extremely powerful static type-system. Although it seems to be restrictive in the beginning, when one gets used to it and knows how to use it for ones help, then it gets rewarding. Our major point was to let the type-system prevent us from introducing side-effects. In Haskell this is only possible in code marked in its types as producing side-effects, so this was something we explicitly avoided and were

able to throughout the whole implementation. Thus arriving at a much safer version in the parallel iteration-strategies with separate threads of execution. This means a user of this approach can be guided by the types and can't abuse them. Thus the lesson learned here is that *if one tries to abuse the types of the agent-transformer or work around, then this is an indication that the update-strategy one has selected does not match the semantics of the model one wants to implement*. If this happens in Java, it is much more easier to work around by introducing global variables or side-effects but this is not possible in Haskell.

Parallelism and Concurrency is a breeze in Haskell due to its complete lack of implicit side-effects. Adding hardware-parallel execution in the Parallel-Strategy required the adoption of only 5 lines of code and no change to the existing Agent-Code at all (e.g. no synchronization, as there are no implicit side-effects). For implementing the Concurrent Strategy we utilized the programming model of Software-Transactional-Memory (STM). The approach is that one optimistically runs Agents which introduce explicit side-effects in parallel where each Agent executes in a transaction and then to simply retry the transaction if another Agent has made concurrent side-effect modifications. This frees one from thinking in terms of synchronization and leaves the code of the Agent nearly the same as in the Sequential Strategy.

Deficits Performance is an issue. A real-time simulation of 2000 Agents in our Haskell solution as opposed to 100.000 in our Java solution is just bad. It is important though to note, that being Haskell-beginners, we are largely unaware of the subtle performance-details of the language thus we expect to achieve a massive speed-up in the hands of an experienced programmer.

Another thing is that currently only homogeneous agents are possible and still much work needs to be done to capture large and complex models with heterogeneous agents. For this we need a more

robust and comprehensive surrounding framework, which is already existent in the form of functional reactive programming (FRP). Our next paper is targeted on combining our Haskell solution with an FRP framework like Yampa (see further research).

Our solution so far is unable to implement the Sequential Strategy with immediate message-handling. This is where object-orientation really shines and pure functional programming seems to be lacking in convenience. A solution would need to drag the collection of all Agents around which would make state-handling and manipulation very cumbersome. In the end it would have meant to rebuild OO concepts in a pure functional language, something we didn't wanted to do. For now this is left as an open, unsolved issue and we hope that it could be solved in our approach with FRP (see future research).

Natural Strategy The most natural strategy would be the Parallel-Strategy as it lends itself so well to the concepts of pure functional programming where things are evaluated virtually in parallel without side-effects on each other - something which resembles exactly the semantics of the Parallel-Strategy. We can also argue that the Concurrent - Strategy is also very natural formulated in Haskell due to the availability of STM, something only possible in a language without implicit side-effects as otherwise retries would not be possible.

5.3 Scala with Actors

This multi-paradigm functional language is included to test the usefulness of the *Actor Strategy* for implementing ABS. The language comes with an Actor-library inspired by [2] and resembles the approach of Erlang which allows a very natural implementation of the strategy.

Ease of Use We were completely new to Scala with Actors although we have some experience using Erlang. We found that the language has some very nice mixed-paradigm features which allows to program in a very flexible way without inducing too much restrictions on one.

Benefits Formulating Agent-behaviour is extremely convenient, especially for simple state-chart Agents. The Actor-language has a built-in feature which allows to change the behaviour of an Agent on message reception where the Agent then simply switches to a different message-handler, allowing elegant implementation of state-charts.

Performance is very high. We could run simulations in real-time with about 200.000 Agents concurrently, something the run-time system easily manages. Also it is very important to note that one can use the framework Akka to build real distributed systems using Scala with Actors so there are potentially no limits on the size and complexity of the models and number of agents one wants to run with it.

Deficits Care must be taken not to send references and mutable data, which is still possible in this mixed-paradigm language.

Natural Strategy The most natural strategy would be of course the Actor Strategy and we only used this Strategy in this language to implement our Models. Note that the Actor Strategy is the most general one and would allow to capture all the other strategies using the appropriate synchronization mechanisms.

6 Conclusion

In this paper we presented all possible general update-strategies for an ABM/S and discussed their implications. Again we cannot stress enough that selecting the correct update-strategy is of most importance and must match the semantics of the model one wants to implement.

We also argued that the ABM/S community needs a unified terminology of speaking about update-strategies otherwise confusions arise and reproducibility suffers. We proposed such a unified terminology on the basis of the general update-strategies and hope it will get adopted.

To put our theoretical considerations to a practical test we implemented them in three very different

kind of languages to see how each of them performed in comparison with each other in implementing the update-strategies. To summarize, we can say that Java is the gold-standard due to convenient synchronization primitives built in the language. Haskell really surprised us as it allowed us to faithfully implement all strategies equally well, something we didn't anticipate in the beginning of our research. Finally we can say that the usage of Scala with Actors: extremely elegant solutions possible when one is willing to sacrifice reproducibility due to non-determinism.

7 Further Research

7.1 Functional Reactive Programming

The implemented framework in Haskell is lacking features like TODO and is basically an attempt of reinventing Functional Reactive Programming (FRP). We were aware of the existence of this paradigm, especially the library Yampa, but decided to leave that one to a side and really keep our implementation clear and very basic. The next step would be to fusion our implementations with Yampa thus leveraging both approaches from which we hypothesize to gain the ability to develop much more complex models with heterogeneous agents.

7.2 Functional Model-Specification Language

After showing that Haskell is a very attractive alternative to existing object-oriented approaches in implementing ABS we are interested whether the declarative power of the pure functional language can be utilized to write specifications for simple ABS models which can be directly translated to our Haskell implementation - if a model specification language is possible which is (very close to) the program-code.

7.3 Actor Model in ABS

We find that the Actor Model should get more attention in ABM/S and although we showed that the Act-Strategy implemented in Scala with Actors can implement very different kind of Models we barely scratched the surface. We hope that more research is going into this topic as we feel that the Actor-Model has a bright future ahead due to the ever increasing availability of massively parallel computing machinery. TODO: mention the work on Erlang in ABM/S
